

Baldness/delocalization in intersecting brane systems

Amanda W. Peet

Abstract. Marginally bound systems of two types of branes are considered, such as the prototypical case of $Dp+4$ branes and Dp branes. As the transverse separation between the two types of branes goes to zero, different behaviour occurs in the supergravity solutions depending on p ; no-hair theorems result for $p \leq 1$ only. Within the framework of the AdS/CFT correspondence, these supergravity no-hair results are understood as dual manifestations of the Coleman-Mermin-Wagner theorem. Furthermore, the rates of delocalization for $p \leq 1$ are matched in a scaling analysis.

Contribution to the proceedings of “Strings ’99”; based on [1] written with D. Marolf.

1. Introduction

No-hair theorems appear prominently in the study of black holes. They are, however, not general; assumptions about the field content of the action are required.

In the supergravity approximation to string theory, there are black p -brane solutions available as well as black holes. Certain systems involving two types of BPS branes are marginally bound, stable at any transverse separation. Supergravity solutions which are fully localized are known for some of these systems, albeit rarely in terms of elementary functions. In this article we will use the method of Surya and Marolf [2] to exhibit the behaviour of the solutions as the separation goes to zero, and to derive no-hair theorems.

The AdS/CFT correspondence [3, 24] is a duality between gauge theories on p -branes and the near-horizon limit of the corresponding supergravity solutions. We discuss this limit of the supergravity solutions for the intersecting brane systems of interest, and we find the dual phenomenon to the no-hair theorems to be the Coleman-Mermin-Wagner theorem [4, 5], viz. the lack of superselection sectors in low-dimensional quantum field theories. We also show that the delocalization rates obtained from a scaling analysis in the field theory are captured by the supergravity; in particular, the strong sensitivity to the dimension p . We end with remarks about future directions.

2. Baldness, a.k.a. supergravity no-hair theorems

One context in which a black hole no-hair theorem in General Relativity may be seen is a process in which a small extremal black hole of charge q is brought up to the horizon of a large extremal black hole of charge $Q \gg q$. Since the geometry for the two extremal black holes is static for any finite separation Δ , this system can be easily studied at any Δ . As the separation $\Delta \rightarrow 0$, the configuration becomes spherically symmetric. The theory does not allow the small charge to end up localized on the horizon of the large black hole.

More generally, finding localized solutions in supergravity is difficult. As a very simple example, consider taking the Dp -brane supergravity solution and performing T-duality along a worldvolume direction, say x_p . Use of the Büscher rules results in a solution that looks like a $Dp-1$ -brane, except that it possesses only a transverse $SO(8-p)$ symmetry instead of $SO(9-p)$. In other words, the harmonic function falls off like r^{p-7} instead of r^{p-8} . This solution corresponds to the *smeared* $Dp-1$ -brane. Of course, we know what the unsmeared $Dp-1$ -brane solution looks like in this case, but more generally the unsmeared version of a smeared solution cannot be successfully guessed. The point of view which we advocate in this article is that sometimes unsmeared supergravity solutions do not in fact exist, for reasons that become clear in the context of the generalized AdS/CFT correspondence.

In the following analysis we are interested in BPS systems comprising two clumps of branes which are marginally bound to each other. The prototype of this system is the $D0 \parallel D4(0)$, and under dualities this is connected to $Dp \parallel Dp+4$, $Dm \perp Dn(p)$, $m+n=p+4$ e.g. $D2 \perp D2(0)$, $F1 \perp Dp(0)$, $Dp \perp NS5(p-1)$, and so on.

Supergravity solutions for such systems have been studied by many groups; a partial list is [6]–[17],[18], see [1] for other references. For purposes of orientation we briefly review the features relevant for our discussion here. Maintaining some generality for the moment, we let there be two types of branes, DA and DB , with common directions $t, \mathbf{z}_1$, relatively transverse worldvolume directions $\mathbf{z}_a, \mathbf{z}_b$ respectively, and overall transverse coordinates $\mathbf{x}_\perp$. We use the “harmonic function rule” [10] ansatz; suppressing the R-R gauge potentials this is

$$\begin{aligned} ds^2 = & H_A^{-1/2} H_B^{-1/2} (-dt^2 + d\mathbf{z}_1^2) + H_A^{1/2} H_B^{-1/2} (d\mathbf{z}_b)^2 \\ & + H_B^{1/2} H_A^{-1/2} (d\mathbf{z}_a)^2 + H_A^{1/2} H_B^{1/2} (d\mathbf{x}_\perp^2); \\ e^\Phi = & g_s H_A^{(3-A)/4} H_B^{(3-B)/4}. \end{aligned} \quad (2.1)$$

Allowing the branes to have harmonic functions that depend on all coordinates transverse to them, i.e. $H_A = H_A(\mathbf{x}_\perp, \mathbf{z}_b)$, $H_B = H_B(\mathbf{x}_\perp, \mathbf{z}_a)$, the equations of motion become (see, for example, [11])

$$\begin{aligned} [\partial_\perp^2 + H_B \partial_b^2] H_A(\mathbf{x}_\perp, \mathbf{z}_b) &= q_A \delta(A); \\ [\partial_\perp^2 + H_A \partial_a^2] H_B(\mathbf{x}_\perp, \mathbf{z}_a) &= q_B \delta(B); \\ (\partial_b H_A)(\partial_a H_B) &= 0. \end{aligned} \quad (2.2)$$

From the last equation, it is clear that one clump of branes, say the A-branes, is necessarily delocalized along the worldvolume of the other clump. For the prototype D0||D4 this is no restriction because there are no z_b . However, for an orthogonal intersection such as D2⊥D2(0) this is a restriction on the generality of the ansatz; we will remark on the case of orthogonal intersections in the last section. Relabeling the $Dp + 4$ brane the ‘big’ brane and the Dp the ‘wee’ one, and $z_a \equiv z$, our basic supergravity equations become

$$\begin{aligned} [\partial_\perp^2] H_{\text{big}}(\mathbf{x}_\perp) &= q_{\text{big}} \delta(\text{big}) ; \\ [\partial_\perp^2 + H_{\text{big}}(\mathbf{x}_\perp) \partial_z^2] H_{\text{wee}}(\mathbf{x}_\perp, z) &= q_{\text{wee}} \delta(\text{wee}) . \end{aligned} \quad (2.3)$$

The first equation is the usual one for the big branes. The second equation is more difficult to solve; here we will use the method of Surya and Marolf [2].

We can now pose the problem in which we are interested. Consider the setup of N_{big} big branes with N_{wee} wee branes separated from them in the transverse direction by Δ .

Figure 1: the setup for our problem of interest.

The $Dp+4$ -branes are displaced from the Dp -branes by Δ .

What we wish to know is whether the wee brane can be localized in the worldvolume of the big brane as the separation is taken to zero, in the supergravity regime.

To motivate this, consider the simple and familiar example of the D-instanton in the background of the D3-brane. The supergravity solution is known explicitly only in the near-horizon region of the D3-brane, which is $\text{AdS}_5 \times S^5$, [21] (see also [19, 20])

$$\begin{aligned} dS^2 &= H_{-1} (\text{AdS}_5 \times S^5) ; \quad \exp(\Phi) = g_s H_{-1} ; \quad \text{where} \\ H_{-1} &= 1 + \frac{3N_{-1}}{16\pi^6 N_3^2 g_s^2} \frac{\rho^4 \rho_0^4}{[\rho_0^2 + |\mathbf{x} - \mathbf{x}_0|^2]^4} . \end{aligned} \quad (2.4)$$

Here, the D-instanton position in Euclidean 10-space is $(\mathbf{x}_0, \rho_0)$, and the IR/UV relation relates ρ to the usual radial coordinate $U = r/\ell_s^2$ via

$$\rho_0 = \frac{\sqrt{4\pi g_s N}}{U_0} = \frac{\sqrt{4\pi g_s N \ell_s^4}}{\Delta} = \frac{\mathcal{R}_{\text{AdS}}^2}{\Delta} . \quad (2.5)$$

The quantity ρ_0 is identified [21] as the scale size of the instanton in the gauge theory. Normally, the IR/UV relation is interpreted as saying that the instanton scale size ρ_0 goes to zero as the D-instanton goes to the boundary. In the context of our problem of interest, however, we are interested in the other end of things: as $\Delta \rightarrow 0$, $\rho_0 \rightarrow \infty$. An alternative way to see that the D-instanton delocalizes without the AdS/CFT baggage

is simply to stare at the supergravity harmonic function for the D-instanton: as the separation $\Delta \propto 1/\rho_0 \rightarrow 0$, H_{-1} loses all information about the relatively transverse coordinates $\mathbf{x}$

$$H_{-1} \xrightarrow{\Delta \rightarrow 0} 1. \quad (2.6)$$

This is a no-hair theorem as, if this $\mathbf{x}$ information had not been erased, we could have used the above process to build black D3-branes with D-instanton ‘hair’ in the form of an arbitrary distribution of D-instanton charge.

Note that in our analysis our solutions will always be taken to be such that they can be matched onto the full asymptotically flat solutions. This means that in any p -brane AdS/CFT correspondence we are doing gauge theory on R^p . As mentioned in [1], this condition rules out some known near-horizon supergravity solutions [22]; it would be interesting to learn what interpretation these solutions may have in another context. At this point we also mention that there are some other known solutions which are not of the type we want. Some are partially localized, but typically these are B scher T-dual to larger-brane solutions. In addition, from the second equation of motion in (2.3) it is possible to see that we can trade some transverse localization for worldvolume localization. Since this does not maintain the integrity of the dimension of bigger brane in the solution, we will not consider these either.

Let us recap the solution for the harmonic function of the big $(Dp + 4)$ branes. We have

$$\partial_{\perp}^2 H_{\text{big}} = q_{\text{big}} \delta(\mathbf{x}_{\perp}) \quad \Rightarrow \quad H_{\text{big}} = 1 + \frac{c_{p+4} g_s N_{p+4}}{|\mathbf{x}_{\perp}|^{3-p}}, \quad (2.7)$$

where $c_p = (2\pi)^{(5-p)/2} \Gamma[(7-p)/2]$. For the wee branes,

$$[\partial_{\perp}^2 + H_{\text{big}}(\mathbf{x}_{\perp}) \partial_z^2] H_{\text{wee}}(\mathbf{x}_{\perp}, \mathbf{z}) = q_{\text{wee}} \delta(\mathbf{x}_{\perp} - \mathbf{\Delta}) \delta(\mathbf{z}). \quad (2.8)$$

Surya and Marolf’s method [2] for solving this equation of motion involves doing a Fourier transform in the four relatively transverse $\mathbf{z}$ coordinates, and it allows transverse separation $\mathbf{\Delta}$. The Fourier transform converts the $\mathbf{z}$ derivative into a wavevector, and the equation can then be solved Fourier mode by Fourier mode. It can also be shown that in order to track the behaviour of each Fourier mode at small separation $\mathbf{\Delta}$, keeping the spherically symmetric modes suffices. Then the equation reduces to a second order ODE in the radial variable $r = |\mathbf{x}_{\perp}|$; this can be solved explicitly and matched across the δ -function. The resulting Fourier series/transform can be shown to converge absolutely, except of course at the location of the δ -function. For details, the reader is referred to the original paper [1].

The results obtained by this method give distinctly different behaviour depending on p [1]:

$$\begin{aligned} -1 \leq p \leq 1 : & \text{ baldness;} \\ p = 2 : & \text{ hair.} \end{aligned} \quad (2.9)$$

(Recall that we are not going higher than $p = 2$ because we take the big-brane, which has dimension $p + 4$, to be asymptotically flat.) For a previous idea on expectations based on the dimensionality p see [23].

From the supergravity perspective these hair/baldness results come about because of the different character of the differential equations with $1/r$ versus stronger potentials $1/r^{n>1}$. Note also that the result for $p = 2$ meshes nicely with the existence of an explicit analytic solution found in [18], viz. D2-branes inside D6-branes, in the near-horizon limit of the D6-brane.

We can actually do better than deriving no-hair theorems for the low-dimensional cases; we can also work out the *rates* of delocalization of the wee-branes as they approach the big-branes. These may be computed by sitting out at a fixed transverse distance from the big-brane, which we choose to be the characteristic supergravity radius $R_{p+4} = \ell_s (g_s N_{\text{big}})^{1/(3-p)}$, and watching the behaviour of the different Fourier modes of the fields of the wee-brane in the $\Delta \rightarrow 0$ limit. The delocalization can thereby be characterized by a distance scale δz . From the supergravity equations we thusly find the scaling [1]

$$\begin{aligned} p = -1 : \quad \frac{\delta z}{\ell_s} &\sim (g_s N_3)^{1/2} \left[\frac{\ell_s}{\Delta} \right]; \\ p = 0 : \quad \frac{\delta z}{\ell_s} &\sim (g_s N_4)^{1/2} \left[\frac{\ell_s}{\Delta} \right]^{1/2}; \\ p = 1 : \quad \frac{\delta z}{\ell_s} &\sim (g_s N_5)^{1/2} \left\{ \log \left[\frac{(g_s N_5)^{1/2} \ell_s}{\Delta} \right] \right\}^{1/2}. \end{aligned} \tag{2.10}$$

The result for the D-instanton agrees with the IR/UV relation, which is a consistency check. The other relations look suspiciously like low-dimensional quantum field theory relations, and we will confirm this later in a precise fashion. We will also see why the no-hair theorems depend so strongly on the dimension p .

3. The AdS/CFT correspondence and the CMW theorem

We would now like to define an AdS/CFT correspondence for this system of two types of branes by analogy with [3, 24]; see also [25]. Of course, the gauge couplings on the big and wee branes are built out of the same string theory parameters, $g_{\text{YM}}^{2(p)} = (2\pi)^{p-2} g_s \ell_s^{p-3}$. The decoupling limit à la Maldacena can be cast in dimensionless statements as follows: $(E \ell_s) \rightarrow 0$, $E \sim U = r/\ell_s^2 \sim \Delta/\ell_s^2$. Now, since the dimensionless gauge coupling is formed by factoring in $p-3$ powers of the typical gauge theory energy E [24],

$$g_{\text{eff}}^2 = (2\pi)^{p-2} g_s (E \ell_s)^{p-3}, \tag{3.1}$$

the physics in the low-energy or decoupling limit will depend on which dimensionless coupling we keep fixed. Since we wish to keep the physics of the big-brane in the game, we keep the big-brane coupling fixed and so the wee-brane coupling will go to infinity in this limit, at ‘fixed’ energy E . Simply put, the big-brane physics is irrelevant in the infrared. Thus, the field theory that we will be interested in is $p+1$ dimensional.

We also need to pin down the other parameters. Since we want to be in the supergravity regime, we will keep $N_{\text{wee}}, N_{\text{big}} \gg 1$ but introduce no particular hierarchy

between them. We also choose to keep the relative four-volume V_4 ‘fixed’, i.e. we will not scale it to zero as ℓ_s^4 . We are most interested in the case where the big-brane is non-compact, i.e. $V_4 \rightarrow \infty$. In the context of the $\text{AdS}_5 \times S^5$ correspondence, this means having only a finite number of D-instantons. However, in our supergravity analysis we can also handle the case of finite-volume, which in the $\text{AdS}_5 \times S^5$ case corresponds to a finite density of D-instantons per unit D3-worldvolume; see [26] for an analysis of this system.

3.1. The supergravity side

Taking the decoupling limit of our supergravity solution makes the big $(p+4)$ -brane go near-horizon; we lose the 1 in its harmonic function H_{big} ,

$$H_{\text{big}} \longrightarrow \frac{1}{\ell_s^4} \frac{c_{p+4}}{(2\pi)^{p+2}} \frac{N_{p+4} g_{\text{YM}}^{2(p+4)}}{U^{3-p}}. \quad (3.2)$$

The more interesting issue is what happens to the wee-brane. Our solution retains dependence on the separation Δ . For the cases which delocalize, we can analyze the harmonic function for the wee-brane near the core of the big-brane. We find by careful attention to boundary conditions that we must *not* drop the 1 in the harmonic function for the delocalizing wee-brane [1]. See also [27] for similar conclusions on this issue. This phenomenon of not losing the 1 we saw very explicitly for the case of the D-instanton in the near-horizon region of the D3-brane, again a consistency check. (For the $p = 0$ system, in a sense we are operating “half-way” between a probe calculation where $H_0 = 1$ and a DLCQ calculation where the 1 in the supergravity H_0 is dropped at the outset.)

In addition, upon checking the dilaton and metric curvatures, we find that the delocalizing wee-brane has a minor effect [1]; it does not change the region where the curvature becomes large, and the region where the dilaton becomes large occurs only extremely close to the wee-branes - the presence of the big-brane transversely shrinks the strong-dilaton region that occurs for $N_{\text{big}} = 0$.

Note also that for the case of finite V_4 it turns out that, as $\Delta \rightarrow 0$, we recover the smeared solution in which $H_{\text{wee}} \propto 1/U^{3-p}$ just like H_{big} .

3.2. The field theory side

In the decoupling limit, the coupling between bulk and brane physics vanishes. In the $p+1$ dimensional field theory, decoupling occurs between the Higgs and Coulomb branches, even quantum mechanically [28]. For our situation where we are near-horizon for the big-brane, we are in the Higgs branch of the field theory. The field content may be recalled by remembering that the Dp branes can be thought of as instantons in the $Dp+4$ -brane; the $p+1$ dimensional field theory is the theory of the collective modes of these instantons. As reviewed in [29] (see also [30],[31]), the fact that the wee-brane gauge coupling goes to infinity at fixed energy in our scaling limit means that some fields, which correspond to the $p-p$ strings which are transverse scalars, become auxiliary and

may be integrated out. The resulting theory is a nonlinear sigma-model. (See also [32] for an analysis in a different regime, where different fields may be integrated out.)

The degrees of freedom of our Higgs branch theory are the instanton scale size and orientation, and center of mass position. In addition, the theory is very strongly coupled because we are working in the supergravity regime. Let us concentrate on the instanton scale size mode, which take as a proxy for how delocalized the wee-brane is. In low-dimensional quantum field theories, the Coleman-Mermin-Wagner theorem prevents superselection sectors in the quantum regime. This theorem then tells us that we have wild infrared fluctuations leading to complete delocalization for $p \leq 1$, i.e. baldness. For $p \geq 2$ superselection sectors are allowed quantum mechanically, so that we have hair for $p = 2$. These results are in direct accord with the supergravity results, as we promised earlier.

In fact, we can go further and use scaling arguments to compute in the low-dimensional field theories estimates for the delocalization rates. As the separation $\Delta \rightarrow 0$, the IR fluctuations will become stronger and stronger, and eventually give complete delocalization. Let us take the IR cutoff to be

$$\Lambda_{\text{IR}} = \frac{\Delta}{\ell_s^2}. \quad (3.3)$$

In a sense we are reconstructing a field that was integrated out by putting back this IR cutoff; see also [29] for a more quantitative discussion on this point.

We now wish to calculate a rms value for the instanton scale size. We first treat the case of the D0-brane inside the D4-brane. For a single D0 instanton the moduli space metric is flat; we will assume that for large- N_0 the free-field approximation works as well, possibly modulo $1/N$ corrections which we will not worry about. Also we assume that each instanton fluctuates independently but has approximately the same size - this latter assumption is motivated by the work of [33] on D-instantons in the original $\text{AdS}_5/\text{CFT}_4$ correspondence. Then, roughly speaking, since each instanton has N_4 directions in the gauge group in which to point, since the action has a normalization factor $g_s \ell_s$, and introducing Λ_{IR} by dimensional analysis gives

$$\begin{aligned} \langle \rho^2 \rangle &\sim N_4 g_s \ell_s \Lambda_{\text{IR}}^{-1}, \quad \text{i.e.} \\ \left. \frac{\sqrt{\langle \rho^2 \rangle}}{\ell_s} \right|_{\text{D0}} &\sim (g_s N_4)^{1/2} \left[\frac{\ell_s}{\Delta} \right]^{1/2}. \end{aligned} \quad (3.4)$$

This agrees with the supergravity result, as we are taking the rms instanton scale size as a proxy for δz . It also agrees with a relation derived in [29]. (We remark here that this delocalization is not in contradiction with localization of center of mass modes for wee-branes without big-branes present which occurs in accordance with the existence of localized supergravity solutions for wee-branes by themselves. The difference in the current context is partly in a factor of order $1/N_{\text{wee}} \ll 1$. So even though it is possible that the CM modes may be localized for the wee-brane instantons inside the big-branes, the fact that the scale sizes are totally delocalized is enough to conclude that we have agreement with the supergravity results.)

For the $p = 1$ case, by similar reasoning we get

$$\langle \rho^2 \rangle \sim N_5 g_s \ell_s^2 \log \left[\frac{\Lambda_{\text{UV}}}{\Lambda_{\text{IR}}} \right]. \quad (3.5)$$

Taking

$$\Lambda_{\text{UV}} \sim \frac{1}{\ell_s}, \quad (3.6)$$

yields, to the accuracy of our scaling analysis,

$$\left. \frac{\sqrt{\langle \rho^2 \rangle}}{\ell_s} \right|_{\text{D1}} \sim (g_s N_5)^{1/2} \left\{ \log \left[\frac{(g_s N_5)^{1/2} \ell_s}{\Delta} \right] \right\}^{1/2}, \quad (3.7)$$

which again agrees with supergravity. In this case, renormalization effects (which are absent for $p < 1$) complicate the comparison with [29].

Although the case of the D-instanton is rather degenerate, in that the field theory is zero-dimensional, the scaling analysis

$$\langle \rho^2 \rangle \sim N_3 g_s \Lambda_{\text{IR}}^{-2}, \quad (3.8)$$

gives the scale-radius duality relation back again, up to constants:

$$\left. \frac{\sqrt{\langle \rho^2 \rangle}}{\ell_s} \right|_{\text{D-1}} \sim (g_s N_3)^{1/2} \left[\frac{\ell_s}{\Delta} \right]. \quad (3.9)$$

This is a consistency check on our method.

We have seen that the supergravity solutions for the parallel intersections are capable of reproducing the field theory behaviour, which is of course very sensitive to the dimension p . Conversely, the field theory analysis is capable of detecting supergravity no-hair theorems.

4. Orthogonal intersections

So far we have discussed the results of [1] only for the prototypical cases $Dp \parallel Dp+4$. We now discuss briefly the case of orthogonal intersections, and for purposes of illustration we discuss the example of $D2 \perp D2(0)$.

The field theory analysis of the previous section suggests that we can draw hair/baldness conclusions for the near-horizon geometry of the orthogonal intersections as well, by T-duality. What matters is the dimensionality p of the intersection theory. For example, for the $D2 \perp D2(0)$ system which has a 0-dimensional intersection, we expect baldness. More specifically, the mode that used to be the instanton scale size becomes, under T-duality, what might be termed the ‘blow-up’ mode. If we trade the two worldvolume coordinates in each clump of D2-branes (A and B) for a single complex coordinate w so that we have w_A, w_B , then the ‘blowup’ mode ρ appears in the combined worldvolume equation as $w_A w_B = \rho^2$.

Now, in the supergravity regime, we have delocalization, but this applies only to the near-horizon region of the geometry. Let us assume that there is no subtlety in matching

this near-horizon part onto the asymptotically flat part, as the supergravity equations of motion suggest. Then, we can draw conclusions about asymptotically flat supergravity solutions as well. Far away from the intersection, we expect each clump of D2-branes to be localized, as they would be if the other clump were not present. Combined with smearing near the intersection, this gives an overall picture of a supergravity geometry with a ‘fat neck’.

More generally, for the solutions with intersection dimensionality $p \geq 2$, we expect to be able to have a skinny neck, but if $p \leq 1$, we expect a fat neck.

The ansatz we made in setting up our supergravity analysis will not cover the case of fully localized orthogonal intersections, because it requires one clump of branes to be delocalized in the worldvolume of the other clump. Some progress has been made in generalizing the ansatz, see for example [15], but to our knowledge the only explicit solutions obtained so far are perturbative [34]. In that analysis, the ansatz [15] was used, along with source terms motivated by ‘BIon’ physics of [35, 36] and the solutions were obtained to second order. For $p \leq 1$ the second-order perturbations were divergent, even after very careful attention to boundary conditions and singularities, while for $p \geq 2$ they were well-behaved. These results lend support to our field theory expectations. We await future progress in order to hear the final verdict, e.g. to find out ‘how fat is fat’.

The search for various fully localized supergravity solutions is difficult. We would like to advocate the position that some of these solutions may not be found because there is a good field theory reason for them not to exist.

It would be interesting to see how far the results of our work can be generalized. One area of interest is nonextremal systems; work on this is in progress.

Acknowledgments

The author wishes to thank Don Marolf for collaboration on the work presented at the conference. In addition, we wish to thank Ofer Aharony, Micha Berkooz, Per Kraus, Joseph Polchinski, and Herman Verlinde for helpful discussions.
